Publication of King's *A Solution to the Ecological Inference Problem* has rekindled interest in the estimation of unknown cell values in two- and three-dimensional matrices from knowledge of the marginal sums. This paper outlines an entropy-maximizing (EM) procedure which employs more constraints than King's EI method and produces mathematical rather than statistical procedures: the estimates are maximum-likelihood values. The mathematics are outlined, and the procedure's use illustrated with a study of ticket-splitting at New Zealand's first (1996) general election using the mixed-member proportional representation system, for which official figures provide a check against the EM estimate of the number voting a straight party ticket in each constituency.

1 Introduction

THE PUBLICATION IN 1997 of Gary King's *A Solution to the Ecological Inference Problem* promised major breakthroughs in the estimation not only of individual behavior from ecological data but also of spatial variations in that individual behavior. This is illustrated in a recent paper by Burden and Kimball (1998), which used King's procedure to estimate the amount and direction of ticket-splitting in the 1988 U.S. Presidential and Congressional elections. They demonstrated substantial variation in the proportions of Bush and Dukakis supporters who voted for other parties in the 264 House of Representatives and 33 Senate contested seats—which they related to the intensity of Republican and Democratic campaigning in those congressional contests.

The potential offered by King's method is very substantial across a wide range of fields within the social sciences. Its value has been contested, however [see, e.g., the review by Freedman et al. (1988), and King's (1999) response, and Tam Cho (1999)], and other

Authors' note: We are grateful to Paul Harris, the New Zealand Electoral Commissioner, for providing the campaign spending data for each candidate and for computer files containing the election result by constituency, to Phil Whelan, the Chief Electoral Officer, for other data, to Helena Tunstall for preparing the spending data for analysis, and to Nigel Roberts for permission to reproduce Table 2.

in which the three parameters λ , γ , and Φ constrain the distribution of T to the known totals:

$$\begin{aligned}\exp(-\lambda_{ij}) &= A_{ij}V_{ij} \\ \exp(-\gamma_{ik}) &= B_{ik}V_{i.} \\ \exp(-\Phi_{jk}) &= C_{jk}V_{.j}\end{aligned}$$

These are scalars for each row in each state (B_{ik}), for each column in each state (C_{jk}), and for each cell in the national split-ticket matrix (A_{ij}) that ensure that the constraints are met. The maximum-likelihood value for each allocation of T across the v_{ijk} cells is then calculated as

$$v_{ijk} = A_{ij}V_{ij}B_{ik}V_{i.}C_{jk}V_{.j}$$

Calculation of these v_{ijk} values is achieved using the iterative biproportionate matrix scaling procedure described by Bacharach (1970) [this procedure has been used for “smoothing” two-dimensional matrices in political science—Särilvik and Crewe (1983) term it “Mostellerisation”]. The three-dimensional data cube is assembled, and initial estimates of the internal cell values—i.e., of each v_{ijk} value—are added to the cube: the easiest way of doing this is to designate all cell values 1.0. These are then summed across one of the dimensions in the cube, and those sums compared with the relevant constraint values (the “actual” values). If the rows of the matrix for each state were chosen, this would give a matrix of row estimates (ER),

$$ER_{i.k} = \sum v_{ijk} \text{ for all } j \text{ columns in the } k\text{th state.}$$

These are then compared with the relevant constraint for each row, and a row scalar (SR) is produced as a ratio between the sum of the estimates and the actual value—

$$SR_{i.k} = V_{i.k}/ER_{i.k}$$

The cell values are then inflated/deflated by the relevant scalar to give a new estimate of their values,

$$e_{ijk} = v_{ijk} * SR_{i.k}$$

These are then summed across the other two dimensions of the cube, to produce estimates of the column sums (matrix EC) and the slice sums (matrix ES). These are compared with the relevant constraints, to produce a new set of scalars (SC and SS):

$$\begin{aligned}SC_{.ik} &= V_{.ik}/EC_{.jk} \\ SS_{ij.} &= V_{ij.}/ES_{ij.}\end{aligned}$$

The process is then repeated by producing a new set of cell value estimates— e_{ijk} —using one of these two scalars—either

$$e_{ijk} = e_{ijk} * SC_{.jk}$$

or

$$e_{ijk} = e_{ijk} * SS_{.jk}$$

The decision on which to use is determined by a goodness-of-fit statistic; we have used the average difference between the estimated and the constraint sum, expressed as a percentage of the constraint sum.

The procedure continues until a stopping rule is applied—either after a set number of iterations or when each of the two goodness-of-fit statistics is below a predefined maximum—an average of 1%, perhaps. (The third will always be zero, since the cell values have been scaled to fit that set of constraints.)

The EM method differs from King's in one major respect, therefore; it is based on three rather than two sets of constraints. [Constraints along further dimensions can be added (see Johnston et al. 1982).] This is a major advantage over ecological inference (EI) because, in addition to the row and column totals for each slice of the three-dimensional data cube employed in that method, EM also has the sums for each cell on the third face of the cube. This means that the EM estimates are based on additional information, with the likelihood that, as a consequence, they are closer to the "real" numbers than might be the case if EI were used. Other mathematical programming solutions using the row and column constraints only as in EI—as presented by Irwin and Meeter (1969) and McCarthy and Ryan (1976, 1977)—tend to underestimate the off-diagonal cell values—on which see Upton (1978). This could well be the case were they—or King's EI method—applied to that example. In the New Zealand case study presented below, for example, it is unlikely that the estimated amount of split-ticket voting would be as large were it not for the additional information provided by the national split-ticket matrix. Other situations in which a matrix acts as a third set of constraints can be applied, including flow-of-the-vote matrices, showing gross changes in voters' preferences over time, and vote by socioeconomic characteristic matrices. Examples of both are given by Johnston et al. (1988): flow-of-the-vote matrices have the number of votes cast for each candidate/party at each of the two elections for each area as the row and column constraints; vote by socioeconomic characteristic matrices use census or similar data for the relevant areas for the row constraints and vote data for the columns.

One major assumption of the EM method is that there is no three-way interaction involved—that there are no other factors influencing the distribution of elements through the data cube other than those identified by the constraints. It makes no other assumptions about individual behavior and how it may vary from place to place, however. Freedman et al. (1991), for example, have pointed out that studies which use ecological regression to estimate missing values imply a constancy assumption that there is no variation in behavior within each group of voters (apart from random variation) across states (using the terminology applied above) so that the pattern of split-ticket voting would be the same everywhere. They suggest an alternative, neighborhood, model in which "people who live near each other are like each other with respect to . . . voting behavior" (Freedman et al. 1991, p. 682). This allows for "state effects", which may be unique to individual states or which may vary systematically across states—as illustrated in the case study below. The EM method allows for these state effects, within the constraints discussed above; further, the additional constraints not included in King's EI method but incorporated within EM are based on survey data, which Freedman et al. (1991, p. 701) argue "offer a better approach to estimating voting than do models because surveys start from data on individuals". Thus EM, unlike EI (Freedman et al. 1998), is not subject to the criticism that it is based on the constancy assumption: it allows for variation across states that may be consistent with the neighborhood model and provides estimates that can be tested against neighborhood effect hypotheses.

Finally, in contrast to King's EI method, EM is a mathematical rather than a statistical procedure: it produces an exact solution to the problem. Evans (1973) has shown that the biproportional matrix scaling procedure is equivalent to that produced by the transportation problem in linear programming, which seeks to minimize the costs of moving goods/people between origins and destinations. Johnston (1985) discusses the equivalence between EM

and loglinear modeling. Thus there are no error terms associated with the estimates. In many of the applications to electoral data such as that discussed below, however, one of the sets of constraints (almost invariably the slice totals) is based on survey data. These have error terms associated with them, and it could be that a number of matrices consistent with the other constraints could be used in the EM procedure. Each may produce a different set of estimates for each of the internal cell values of the data cube, from which a sampling distribution could be derived. This would be of particular value if the purpose of using the procedure was to estimate particular cell values. In all of the applications to date, however, the goal has been to produce estimates for all cells to allow study of variations across space (of systemwide variations in state effects). For these, the important thing is whether the relative size of the values are the same with different starting constraints, and experiments have shown this to be the case (Johnston and Pattie 1991a). Additional tests could be undertaken by, for example, splitting the states into two or more groups; each would have its own survey-based slice constraints, so that tests for robustness could be conducted depending on the split.

3 The New Zealand Case Study

In 1992 and 1993 the New Zealand electorate voted in two referendums for their electoral system to be reformed; first-past-the-post in single-member constituencies was replaced by an MMP (mixed-member proportional) system akin to that in use in (West) Germany since democracy was reestablished in the 1950s and now used in a substantial number of ex-Communist states (Moser 1999). Just over half of the members of the House of Representatives (65) were to be elected from single-member constituencies by the first-past-the-post system, and the other 55 from national party lists. The electors had two votes, one for the constituency candidate and one for the party list: the final composition of the House of Representatives reflects the proportional distribution of party votes, with each party being allocated additional seats to those which it had won in the constituency contests to achieve the proportional outcome. [On the process involved in the introduction of MMP, see Jackson and McRobie (1998). To be allocated list seats a party must win either at least 5% of the national list votes or one constituency seat.]

This system was used for the first time in 1996 when the general election was contested by seven main political parties/groupings—Labour, New Zealand First, Alliance, National, Association of Consumers and Taxpayers (ACT), United, and the Christian Coalition. The first three of these contested all 65 constituencies in that section of the election, National contested 64, ACT 63, the Christian Coalition 37, and United 25: all seven were on the list for the party votes.

The voting patterns for the two sections of the election are very similar (Table 1: the index of dissimilarity between the two columns is 5.5), with the implication that the majority of electors voted for the same party in both contests. Some split-ticket voting was inevitable because only three of the seven major parties contested every constituency seat, but, in general, it appears from Table 1 as if the great majority of people voted for a constituency candidate from the party that they supported in the party vote contest. This was not the case, however. Before the votes were counted they were divided into two groups: those which were 'straight ticket' (i.e., the same party was supported in both contests) and those which were 'split ticket'. The numbers in each group were tabulated by constituency and published in the Chief Electoral Officer's report on the election. In the country as a whole, only 63% of the valid votes were 'straight ticket'—with the corollary that more than one-third split their votes. Across the 65 constituencies, the percentage of 'straight ticket' votes ranged from a low of only 30.67 to a high of 76.77.

on different criteria. This is illustrated by the row for the ACT in Table 2; of those who voted for National in the party contest, almost two-thirds (65.5%) voted for a National party candidate in the constituency contests—their party votes would win seats allocated according to the list procedure, but they did not expect to get constituency seats. [Their 6.1% of the party votes entitled them to eight seats in the House of Representatives. Seven of these were allocated from the list and one resulted from victory in a constituency contest: their leader won in Wellington Central with 34.8% of the votes (see Fraser and Zangouropolous 1998). Only three other ACT candidates won more than 10% of the constituency votes, and none achieved more than 15%.]

The published election results give the number of votes cast in each constituency both for each candidate in the constituency ballot and for each party in the national list contest. Using those as the column and row total constraints, respectively, and the matrix in Table 2 as the basis for the internal cell constraints (i.e., as the slice of the three-dimensional data cube), we have used the EM method to estimate the split-ticket matrix for each constituency. (The percentages were converted into numbers of votes, consistent with the row and column totals for the whole of New Zealand.) Because not all of the parties contested all of the seats, the interconstituency variations in these estimates are best appreciated by looking separately at different groups of seats. Table 3 presents the summary statistics for the flow variations in the 35 constituencies contested by candidates from National, Labour, New Zealand First, the Alliance, ACT and the Christian Coalition. There are four rows for each matrix cell: the first two give the minimum and maximum percentages, respectively, and the other two give the mean and standard deviation. Thus, for example, the percentage of National loyalists (who voted for National in the party contest and for the National candidates in the constituency contests) ranged from 29.7 to 94.8, with a mean of 74.7 and a standard deviation of 15.2.

The clear impression gained from Table 3 is of very considerable interconstituency variation in the pattern of flows. Most of the standard deviations are large relative to the means, and there are very substantial ranges, even in the percentages who are loyal and who shift between the largest parties. National and Labour were by far the largest in the final outcomes (Table 1): they are also the longest-established parties and were the only contestants for power in the two-party system that dominated New Zealand from the 1930s until the end of the 1980s. Still, in one constituency, as many as 29.2% of National party voters in the list contest gave their support to the Labour candidate in their constituency contest, whereas in another, 23.2% of Labour's party voters in the list contest supported the National candidate for that constituency seat. In the former case (the Waimakariri constituency, on the northern fringe of Christchurch), National obtained 12,824 of the party votes to Labour's 10,631, with no other party getting more than 4100: in the constituency contest there, however, Labour's candidate got 19,875 votes to National's 9269. (The Labour candidate was a former party leader.) In the latter case (Nelson, in the north of the South Island), Labour and National got 11,012 and 10,652 votes, respectively, in the party contest, but National's candidate defeated Labour's by 20,481 to 8057 in the contest for the constituency seat. In both cases, the two parties' candidates were both incumbents: clearly in each there was a strong personal vote for one candidate.

Our major goal in this paper is not to analyze the spatial variations in split-ticket voting in detail but, rather, to illustrate the EM method. Many of the individual features—such as those in Wellington Central, Nelson, and Waimakariri referred to above—reflect particular aspects of the local campaigns, such as the popularity of incumbent candidates. But there may also be systemwide relationships. Burden and Kimball (1998) found very strong relationships between the pattern of split-ticket voting in the 1988 U.S. elections and the volume of

Fig. 1 Regression of estimated on actual number of straight-ticket votes, by constituency—New Zealand 1996 General Election. The regression equation is $Y = 98.70 + 0.96X$ ($SE = 0.04$), with an r^2 of 0.89.

checked against actual data, they are very close to them, allowing us to infer that the values that cannot be checked—the interparty flows—are also excellent estimates of the actual patterns.

4 Conclusions

The twin associated problems of EI and the estimation of known from unknown values have long concerned social scientists interested in, among other things, spatial variations in a wide range of behaviors. The EM method discussed here was introduced to social scientists as a means of estimating traffic flows and other movement patterns, providing maximum-likelihood estimates of flow patterns that could be used in transport planning. [The seminal work was by Wilson (1970); see also Wilson (1981).] It has been applied in a range of studies of electoral behavior, notably in Great Britain (as by Johnston et al. 1988), but also in work on split-ticket voting in the United States (Johnston and Hay 1984), but has not been widely appreciated and adopted. [Johnston and Pattie (1991b), for example, used it to estimate the volume of tactical—or strategic—voting at the 1987 British general election; their estimate has recently been confirmed by Alvarez and Nagler (2000).] This paper has therefore set out the basic procedures involved, illustrated their application with a case study of a novel electoral situation, and reported on a validation exercise that suggests considerable confidence in the estimates produced.

Different estimation procedures make different assumptions and have different data requirements. The EM method reported here requires more data than King's EI procedure,
